Abstract

Objective:
Smoking cessation is crucial for patients with coronary heart disease (CHD), yet depression may impede cessation success. We systematically reviewed the longitudinal association between depression and subsequent smoking cessation in individuals with CHD in order to quantify this effect.

Methods:
Electronic databases (PsychInfo, PubMed, CINAHL) were searched for prospective studies of CHD patients which measured depression at baseline (scales, diagnostic interview or antidepressant prescription) and reported smoking continuation/cessation at follow-up. Inclusive dates were 1st January 1990 to 22nd May 2013. Standardized mean differences (SMD) and associated 95% confidence interval (CI) were estimated using random effects meta-analysis. Sensitivity analysis explored the impact of limiting meta-analysis to studies using different depression measures (validated scales, diagnostic interviews, antidepressant prescription), different durations of follow-up, or higher quality studies.

Results:
From 1451 citations retrieved, 28 relevant articles were identified. Meta-analysis of all available data from 20 unique datasets found that depressed CHD patients were significantly less likely to quit smoking at follow-up (SMD=-.39, 95% CI -.50 to -.29; I²=51.2%, p=.005). Estimates remained largely unchanged for each sensitivity analysis, except for two studies that used antidepressants, which showed a much larger effect (SMD=-.94, -1.38 to -.51; I²=57.7%, p=.124).
Conclusions:

CHD patients with depressive symptoms are significantly less likely to quit smoking than their non-depressed counterparts. This may have implications for cardiovascular prognosis, and CHD smokers may require aggressive depression treatment to enhance their chances of quitting.

Introduction

While smoking cessation should be recommended to all patients (1-3), recent reviews have highlighted the importance of smoking in patients with coronary heart disease (CHD) (4-6). Smoking cessation is associated with 36-50% reduction in morbidity and mortality in CHD patients, with the benefits of quitting smoking outperforming those related to other preventive strategies such as blood pressure or cholesterol control (2, 3). Cessation is especially crucial in this population, as continuing to smoke renders such secondary prevention interventions less efficacious (7, 8), therefore smokers are not deriving the full benefit from preventive therapies. For example, when comparing 4424 treated hypertensives, those who smoked had higher levels of suboptimal diastolic blood pressure 90mmHg or more (33% vs. 25%), along with higher rates of microalbuminuria. Men from the same sample also had higher rates of elevated systolic blood pressure of 140mmHg or more (73% vs. 69%), higher left ventricular hypertrophy, and microalbuminuria, whereas women smokers had higher cholesterol (8). Similarly, Milionis et al. (7) have demonstrated how smokers in primary and secondary prevention statin trials have failed to glean full benefits from these lipid lowering drugs, with smokers having an extra 23-86% increased risk of a cardiovascular event. While having an acute coronary event can motivate smokers to quit, the majority of smokers continue to smoke or resume smoking within 6 months after such events (6), therefore identifying factors that predict relapse is of significant value for clinicians.
The prevalence of depression in patients with coronary heart disease (CHD) is elevated in comparison to general population samples (9, 10). Tobacco use has a long-established relationship with depression. Those who smoke have a higher incidence of depressive symptoms, and those with depressive symptoms are less likely to quit smoking and are more likely to relapse if they do (4-6). For example, secondary analysis of a randomised trial on smoking cessation showed that a greater number of nicotine withdrawal symptoms experienced by depressed smokers, as opposed to non-depressed smokers, mediated the effect of depression on smoking continuation 3-months later. Indeed, this was estimated to account for 27% of the effect of depression on cessation outcomes (11). It also appears that treating depression in patients with MI may not increase cessation rates (12), and it is unclear whether quitting smoking leads to an improvement in or worsening of depressive symptoms (13).

Therefore, the effect of depression on subsequent cessation may be profound, however, this has not been subject to systematic review or meta-analysis. The American Academy of Family Physicians have described the research on the impact of depression on lifestyle modifications as “low quantity medium to low quality evidence”, and they suggest that further investigation is required (14). Meta-analysis should provide a more precise effect estimate than single studies alone. We quantified the effects of depression on subsequent smoking in patients with CHD. However, as depression is defined in different ways, the potential for misclassification error is high which has the potential to distort estimates of the exposures effect (depression) on the outcome (smoking), thus resulting in biased estimates of the effect of depression.
Similarly, the impact of depressive symptoms may fluctuate over time, or study quality could be heterogeneous. We planned a number of sensitivity analyses to address these potential biases.

**Methods**

This systematic review with meta-analysis was performed according to recommended principles (15).

**Search strategy**

A systematic literature search of PubMed, CINAHL and PsychInfo was conducted in May 2013. Searches used subject headings and keywords. A PubMed example is as follows: ((("Depression"[Mesh] OR "Depressive Disorder"[Mesh] OR "Depressive Disorder, Major"[Mesh] OR "Adjustment Disorders"[Mesh])) AND "Myocardial Ischemia"[Mesh]) AND ("Smoking"[Mesh] OR Smok*)). This search was supplemented by handsearching references of retrieved articles. Studies dating from the 1\textsuperscript{st} January 1990 to May 2013 were included in the analysis.

**Study selection and data extraction**

Studies were included if they met the following eligibility criteria: CHD samples, published in 1990 or later, prospective, measure of depression at baseline (i.e. diagnostic interview, questionnaire, antidepressant prescription, single-item questions), measure of smoking at follow-up. We included control groups from (non)randomized trials, or combined intervention and control groups from (non)randomized trials (where
data for the control groups could not be obtained). We excluded papers which had samples exclusively enrolled in cardiac rehabilitation (CR) programs for two main reasons. Such programs may have intense behavior modification elements, and should have standard measurements of depression and smoking at baseline and outcome. Thus, a large body of data exists, but is not necessarily reported in each paper on CR. Furthermore, CR participants are not representative of general CHD patients for many reasons: not all CHD patients are referred to CR; not all referred patients attend CR; those who do attend often drop out; and depression has been shown to predict non-attendance and drop-out, which may bias estimates (16-18). Two reviewers independently completed the first screening of abstracts/titles (DR, AR). Studies that were considered eligible for inclusion were read in full and suitability for inclusion was independently determined by DR and AR. Disagreements were managed by consensus or discussed with a third reviewer (KM or FD). Data were extracted on the basis of study setting, % men, length of follow up, depression measures, smoking status (or relevant results). Authors were contacted to provide further information when there was insufficient data provided in the published paper.

**Quality assessment**

The quality of the studies was assessed using the Crowe Critical Appraisal Tool (CCAT) (19-21), which was developed based on existing tools, general research methods theory and reporting guidelines. It has exhibited a good degree of construct validity (19) and reliability (21), and is reported to be simple to implement and suitable for all research designs in health. The CCAT consists of eight categories corresponding to various
aspects of a study, including introduction, design, sampling, data collection, ethical matters, results and discussion. Each category contains a number of items, which are marked as present, absent, or not applicable, with only those items that are applicable to a specific research design being included in the appraiser’s score. Each category is also scored on a scale from 0 (no evidence) to 5 (highest evidence). Scoring is thus not based solely on a checklist, but allows for a combined objective (tick boxes) and subjective scoring of each category (19). The authors recommend publishing individual category scores along with total scores so that weak scores in a category are not obscured. Total scores for each study (ranging from 0-40) are presented as a percentage.

**Statistical analysis**

Smoking status at follow up was the primary outcome of interest. As some studies used multiple measures of depression, these were considered in the following hierarchical manner: diagnostic interview, validated scale, current prescription of antidepressants, history of depression, single-item (unvalidated) measure. Due to differential measurement and reporting of smoking status (e.g. current/former/ex-smoker; smoking at least 20 cigarettes in a year) and depression (e.g. scoring above threshold on a scale; mean and SD of depression scale for continued smokers and quitters), the unadjusted standardized mean difference between depressed and non-depressed samples was the primary measure of effect. This was estimated for all included studies using the *metaeff* (22) command in Stata 12.1, and estimated using the random effects model (23, 24). The $I^2$ test was used to assess the percentage of variability in the effect
estimates that can be attributed to heterogeneity (variation in effect estimates arising from methodological or clinical differences between studies) rather than chance. Pre-planned sensitivity analysis included examining the impact of differential depression assessment (validated scales, diagnostic interviews, antidepressant prescription), different durations of follow-up (categorized as <1 year versus ≥1 year), or higher quality studies (≥60%) (24). We also assessed whether study design, or the use of adjusted or unadjusted estimates affected results. Formal statistical testing for publication bias or small study effects was conducted using the Egger’s test which is a sensitive regression asymmetry test. Bias is detected by determining whether the intercept deviates significantly from zero in a regression of standardized effect estimates against their precision.

Results

Study identification

A flow diagram of the search strategy is presented in Figure 1. The search yielded 1185 papers of which 1165 were excluded. Twenty-eight explored the association between depression and subsequent smoking (11, 12, 25-50). Nine more were omitted (four repeat publications (38, 44-46), unavailable data (12, 47, 48, 50), one had too few smokers to provide an estimate (49) - see Appendix A). McGee et al. (37) was treated as two studies, as two depression scales were used in independent groups to predict smoking. This left 20 datasets from 19 articles for analysis.
Characteristics of included studies are displayed in Table 1, with studies listed in alphabetical order of first author.

Study Characteristics

Patients were recruited in hospital settings across 9 countries. Sample sizes at follow-up ranged from 20–1276. The majority of samples are from patients who presented with acute CHD, with the remainder consisting of two studies including both acute and chronic CHD patients, two studies with CHD outpatients, and one study being unclear (those diagnosed with coronary artery disease after angiography). Length of follow-up varied from 1 month to 13 years. Various methods were used to assess depressive symptoms, with six studies (30, 31, 33, 37, 41, 43) utilizing more than one measure. Two studies used diagnostic interviews (41, 43), 17 used validated scales (11, 26, 27, 29-37, 39-43), two used antidepressant prescription (25, 30), and one used a single-item measure of mood (28). Quality appraisals are available in Appendix B.
Meta-analysis

Using the depression measure hierarchy outlined in the Methods, the forest plot using the best estimate from individual studies is displayed in Fig 2.

Fig 2 here

Overall, there is a small effect of depression on cessation across the 20 datasets (SMD=-.39, 95% CI -.50 to -.29). There was statistically significant heterogeneity evident ($I^2=51.2\%, p=.005$). There was no evidence of funnel plot asymmetry indicating that the effect of depression on smoking identified in smaller studies was not different to larger studies ($p=.071$ for Egger’s test of asymmetry; see Appendix C for funnel plot).

Sensitivity analyses

Summary estimates for each of the sensitivity analyses are displayed in Table 2 (and Appendix D):

Table 2 here
Estimates were largely unchanged for each of the above conditions. Two studies that used anti-depressants demonstrated an effect size that was between 2-3 times larger than the other estimates (25, 30). One of these studies contributed to significant heterogeneity in the overall estimate and other sensitivity estimates (25), as when it was omitted the overall effect remained similar but the heterogeneity was no longer significant (SMD=-.34, -.42 to -.26, I$^2=21.9\%$, p=.19). The best estimate from the other study was the depression scale so this was adopted for the other analyses (30).

**Discussion**

Overall, the results of this review suggest that depression is consistently associated with significantly reduced likelihood of subsequently quitting smoking in CHD patients. This is problematic for CHD patients for two reasons. Firstly, smoking cessation benefits CHD patients. Secondly, smoking continuation has a significant negative impact on therapies that reduce hypertension and cholesterol (7, 8). Therefore, it is possible that depressive symptoms may be contributing to higher cardiovascular risk in smokers by reducing the probability of cessation.

**Size of effect**

According to guidelines (24), the effect sizes reported here is ‘small’ for all analyses except when analysis is confined to studies defining depression using antidepressant prescription. However, even the small estimate is likely to be a clinically significant effect, and for example is of similar magnitude to a reduction in post-MI depression post-intervention (51). That large effects were demonstrated for antidepressant
prescription may seem counter-intuitive, as bupropion SR has been shown to increase likelihood of quitting in depressed cardiac patients (11, 52). It is possible that this classification may simply reflect those who have more severe depression and are thus less likely to quit, but more likely to come to clinicians’ attention for depression and receive antidepressants. Furthermore, as antidepressants can be prescribed for other problems (pain, other psychiatric conditions, etc.) in those who may not have depression, it is possible that such conditions also affect smoking behavior. Another explanation is that the classification as depressed for those using antidepressants or sedatives in one of these studies (25) may have significantly inflated the depression category, and possibly lead to an overly-large effect size for that study. However, caution should be used when interpreting these sensitivity analyses, as there were very studies in some categories.

Study quality

Any conclusions drawn from such meta-analyses must be cognizant of the quality of the literature reviewed (24). While critical appraisal of primary studies is an essential feature of systematic reviews, the lack of a ‘gold standard’ appraisal method has been acknowledged (53, 54) with many tools lacking information on development, evaluation of validity or testing reliability (19). Assuming the CCAT ratings were appropriate, this had little effect on our results in sensitivity analyses, and indicates the findings are consistent across studies.
However, other indicators of quality could be considered. Studies largely relied on self-report data, which could be considered a weakness, despite the fact that such data has excellent sensitivity and specificity for smoking behavior (55). The severity of smoking addiction, or number of cigarettes smoked were also typically omitted. Possibly more problematic was that studies differed somewhat in their classifications of smokers, or did not report the precise criteria used to categorize smokers and non-smokers. Furthermore, studies largely did not adjust for other potentially confounding factors when reporting the associations of interest, which means that the present results may be over-estimates. Similarly, the measurement of depression was heterogeneous. Differential measurement of depression can lead to starkly contrasting results when predicting prognosis (56, 57). Reassuringly, sensitivity analyses demonstrated similar effect estimates for all measures, with the exception of anti-depressants. It is crucial that future research adopts recommended definitions of smokers (58), and wherever possible incorporates biochemical measures of smoking, and measures of addiction severity.

**Treatments and hospitalization**

As depression is typically episodic, and chronic, it is possible that the impact of depression on subsequent smoking fluctuates, with the highest influence during more severe depressive episodes (5). However, sensitivity analysis did not show any major effect of follow-up duration on the present results. Given that nicotine is so addictive (and smoking is typically an everyday activity) any hypothesized fluctuating effects may actually be more important for non-addictive behaviors, such as physical activity.
Furthermore, it is possible that depression may have a stronger effect on smoking initiation than cessation (59).

While cessation counseling with more than 1-month follow-up has been shown to be effective for cardiac patients (1), and can even reduce post-discharge mortality when combined with pharmacotherapy (60), no randomized trials have assessed smoking interventions in depressed cardiac patients specifically. Available data is limited to post-hoc analyses, albeit pre-planned (6, 12). Similarly, trials have not examined the safety of nicotine replacement therapies (NRT) in acute cardiac patients, and as nicotine has direct effects on the cardiovascular system, RCTs for acute patients are needed to establish safety (6). These deficiencies in the literature somewhat limit the recommendations that can be made regarding specifically targeting depressed CHD patients who smoke.

In contrast, nicotine replacement therapy (NRT) has been approved for stable CHD patients, and is recommended for selected MI patients as they are being discharged. NRT acts on withdrawal symptoms, so may be especially important for depressed CHD patients who tend to report higher rates of such symptoms (11). Bupropion SR has been shown to be well-tolerated in patients with acute CVD, and to increase subsequent quit rates in those with elevated depressive symptoms compared to those without (19% v 3%), although this was non-significant (p=.07) probably due to limited sample size (11). Although varenicline has demonstrated effectiveness in increasing cessation rates in stable cardiac patients, caution is needed when prescribing this therapy in those with
depression and CHD, due to reported increases in depressed mood and even suicidality, and intensive monitoring would be required (6).

Unfortunately, despite hospitalization being a teachable moment for smoking cessation, healthcare professionals advise patients to quit less often than they should (1, 61, 62). While the results of the present review suggest that depressed CHD patients may require more intensive intervention, the use of systematic programs on cessation seem to be effective, even when controlling for depression (29, 62). Hospitals should implement such systematic programs, and consider screening for depression in smokers to target those in need of more intensive intervention (6).

**Future research**

The present findings suggest that further, more sophisticated research is required on the interactions between depression and smoking. Adding multiple follow-up phases with measures of depression and smoking at each phase would provide more detail on the effects of depression over time (4). While many studies adjust for smoking status at baseline (10), they typically do not account for the number of cigarettes smoked, or whether people quit post event, and therefore the full effects of smoking may not be assessed properly. Such research may also inform the literature on potential behavioral mechanisms linking depression with poorer prognosis in those with coronary heart disease (63, 64), as our results suggest that smoking may be a mediating factor in the depression-prognosis link (65). As results were largely unadjusted, it is possible that other factors account for the depression-smoking association seen here. Depressed
CHD patients have higher cravings, lower confidence in quitting, greater withdrawal symptoms, lower sense of coherence, lower social support than non-depressed smokers (11, 12, 26, 38, 39), and future research should determine the potential interacting effects of these variables. Furthermore, novel therapies such as behavioural activation may need to be investigated, as the efficacy for talk therapies appears to be mixed for depressed patients (4, 12), and our results highlight the need for establishing the best treatments for cessation in depression CHD patients.. Finally, although we studied the association between depression and cessation in CHD patients, future research should establish whether the effects seen here are similar for other populations.

**Strengths and Limitations**

The results should be interpreted in the context of the limitations relating to the original studies. Although the methodological quality of the included studies was reasonable, eight were rated below the threshold of 60%. However, accounting for quality of the included studies in a sensitivity analysis did not change the pooled effect. In addition, our meta-analysis was restricted to the pooling of unadjusted estimates, thereby failing to account for potential confounders. However, the adjusted estimates did not differ greatly. Furthermore, although we were able to consider the effect of misclassification bias due to different depression measures, we were unable to account for the potential influence of different measures of smoking. However, despite the wide variation in smoking measures, the results across the individual studies are quite consistent as displayed in the forest plot, and when the antidepressant studies are removed, the
heterogeneity is no longer significant, thus suggesting the effect is quite robust. There is the possibility that some chance findings are being submitted, or that studies, including those which measure multiple behaviors, are only reporting those with significant associations, and this was supported by some evidence of publication bias. Data were pooled from six different countries, enhancing the generalizability of the findings. Omission of CR programs also weakens the findings.

**Conclusion**

Depression reduces the likelihood of quitting smoking in cardiac patients, and this effect remains after adjustment for other factors. Clinicians should consider screening for depression in smoking patients with CHD, and provide intensive cessation help. It is vital to establish the cessation methods that are most efficacious for depressed CHD smokers.
