Defining and quantifying coping strategies after stroke: a review

C Donnellan, D Hevey, A Hickey, D O’Neill

The coping strategies that people use after a stroke may influence recovery. Coping measures are generally used to assess the mediating behaviour between a stressor (ie, disease or condition) and the physical or psychological outcome of an individual. This review evaluates measures that quantified coping strategies in studies on psychological adaptation to stroke. The main aspects of the coping measures reviewed were (a) conceptual basis; (b) coping domains assessed; (c) coping strategies used after a stroke; and (d) psychometric properties of coping measures used in studies assessing patients with stroke. Four databases (Medline, CINAHL, PsychINFO and Cochrane Systematic Reviews) were searched to identify studies that used a coping measure in stroke. 14 studies assessed coping strategies in patients after stroke. Ten different coping measures were used, and the studies reviewed had many limitations. Few studies provided definitions of “coping” and the psychometric properties of the coping measures were under-reported. The need for future studies to more clearly define the coping process and to present data on the reliability and validity of the measures used is emphasised.

A stroke is a sudden and often traumatic major life event that usually occurs with minimal warning and, for many, results in life-changing consequences with which afflicted people must cope. Stroke is the first leading cause of disability in adults in Western countries and more than one third of people who survive a stroke will have severe disability.1 The increasing size of the older population coupled with the increase in the proportion of people surviving acute stroke means that the number of people learning to cope with stroke-related disability each year is increasing.2

Research on the use of disability-specific coping strategies for other conditions has shown better psychosocial adaptation to disability and chronic illness.3 As neurorehabilitation comprises maximising recovery and adaptation to disability, coping skills may be of importance. Some evidence suggests that coping is likely to predict success in rehabilitation.4 Rehabilitation after a stroke includes more than functional recovery because, in tandem with physical disability, people often experience a variety of psychological sequelae such as depression, anxiety and emotional lability, which can compromise the rehabilitation process and affect long-term adjustment.5–7

Research on stroke is beginning to focus attention on psychological outcomes such as quality of life and subjective well-being8 in addition to survival and functional outcomes. Depression has been most intensively studied,9–13 and other psychological problems dealt with include fear of loss of control,14 fears about death and disfigurement, social isolation, helplessness and worry about loss of social roles.7 A focus on coping with the emotional and cognitive changes after stroke is critical to understanding the rehabilitation process.15

Coping has been a major focus of research in psychology for several decades and in particular in the discipline of health psychology.16 Two of the core theorists in the study of coping, Folkman and Lazarus,17–20 defined coping as “the constantly changing cognitive and behavioural efforts to manage the specific external or internal demands that are appraised as taxing or exceeding the resources of the person”. This definition had a profound effect on the conceptualisation of coping22 and has become widely accepted in the psychological literature.23 Coping strategies refer to the specific efforts, both behavioural and cognitive, that people use to master, tolerate, reduce or minimise stressful events. Two major categories of coping strategies are widely recognised: problem-solving strategies (efforts to do something active to alleviate stressful circumstances) and emotion-focused coping strategies (efforts to regulate the emotional consequences of stressful or potentially stressful events). Some authors have argued for a third dimension of avoidance-oriented coping (efforts to avoid a stressful situation by seeking out other people or by engaging in a substitute task).24–26 The opposite end of the spectrum to avoidance-oriented coping is referred to as active approach-oriented coping.26–28 A distinction is also made between dispositional and situational approaches to coping. The dispositional approach focuses on relatively stable coping strategies used by people across different stressful situations, whereas the situational approach refers to coping as a dynamic process, showing little consistency both across and within stressful situations.28

The Transactional Theory of Stress and Coping, developed by Lazarus and Folkman,17–20 29–30 is the most widely used framework for evaluating the processes of coping with stressful events.31–36
According to this theory, the stressor is initially appraised in terms of personal relevance to the individual and, subsequently, the resources available to deal with the stressor are evaluated. According to de Ridder, the Transactional Theory Papadopoulos encouraged the development of instruments in which subjects were asked to reflect on their conscious efforts to cope with adverse conditions. Several self-report measures of coping now exist—for example, the Ways of Coping Questionnaire (WCQ) and the Coping Orientation for Problem Experiences. Abundant research literature on coping is available in the context of a wide range of illnesses. In the context of stroke, some relatively recent attention has been paid to the issue of coping. To date, however, research findings have not quantified what consistent coping strategies are commonly adopted in the aftermath of stroke. This paper aims to evaluate measures that quantified coping strategies in studies dealing with psychological adaptation to stroke. This review examines the conceptual basis and the specific domains of the coping measures used to assess coping after stroke. It also evaluates the findings in relation to the pattern(s) of coping response in the context of an acute, debilitating condition such as stroke. Psychometric properties of the coping measures will be reviewed with respect to a population affected by stroke, as certain stroke sequelae such as cognitive and language impairments may affect participation in coping assessments or in the process of coping. Identifying adaptive coping strategies that people use after a stroke may facilitate the development of more effective rehabilitation strategies. Coping skills may be considered to be the key psychological resources necessary to rebuild the lives of patients disrupted by the residual deficits of stroke.

**METHODS**

**Search strategy**

A review was conducted of standardised measures of coping used in studies of patients with stroke. A computer search was performed on databases: Medline (1966–February 2006), PsychINFO (1887–February 2006), CINAHL (1967–February 2006) and the Cochrane Systematic Reviews (1993–February 2006). The following keywords were used: “cerebrovascular accident” and “coping” or “adaption, psychological” or “adaptive behaviours” or “reintegration” or “psychological adjustment”. Selected articles were obtained and reference lists in articles were reviewed by the main author to identify additional citations.

**Inclusion criteria**

Articles were included in the review if they fulfilled the following criteria:

a. They published peer-reviewed research.

b. They used standardised questionnaires and measures in cross-sectional, longitudinal and intervention studies.

c. The sample population comprised or included patients with stroke.

d. Data from an instrument quantifying coping were reported.

**ANALYSIS OF PSYCHOMETRIC CRITERIA**

**Reliability**

Two types of reliability were examined in this review: internal consistency and test–retest. Internal consistency is the most common estimate of reliability reported, estimated using Cronbach’s α, which should not fall below 0.7 for research purposes. Although establishing test–retest reliability in the context of research on coping strategies is problematic, because of the inherent potential for variability in coping responses over time, we assessed for the presence (or absence) of data on test–retest reliability: if present, a correlation of ≥0.7 was considered of value.

**Validity**

We reported evidence of construct validity, the extent to which a measure is related to other measures in ways that are consistent with the hypothesised direction. Several different specific categories used to classify types of validity information—for example, correlations with specified variables, correlations with unspecified variables, correlations with other measures, inter-correlations among parts of a measure, comparison of scores between two or more groups and any type of factor analysis—were used as guidelines to report validity of the coping measures in this review.

**RESULTS**

**Overview**

Of 102 studies identified, 14 studies met the inclusion criteria. Table 1 presents a summary of the studies reviewed. Seven studies were cross-sectional in design, five were longitudinal studies and two were intervention studies. The sample type and size varied in different studies. Ten studies conducted research on a population with stroke alongside other patient groups. The remaining eight studies examined coping only in patients with stroke. Seven studies were primarily descriptions of the profiles of coping strategies, and a further three examined the stability of this profile over time. Five of the studies examined the association of various factors (emotionalism, nursing follow-up, depression, training of patient and anxiety) with coping behaviour and two investigated coping as a predictor of outcome. Most of the studies had modest sample sizes, ranging from 30 to 76 participants. The timing of assessment of coping after stroke also varied, ranging from 1 week to 3 years. The mean age (average of reported means) was 65 (SD 8.6) years, with two means identified as outliers (38.6 and 78.1). The sample populations in studies in which mean ages were outliers were not constituted entirely of a population with stroke.

**Conceptual basis**

Five studies defined the term “coping” and four made reference to a coping theory or model. The only consistent definition of coping used in three of the studies was that by Lazarus and Folkman. Two other studies used definitions that have some resemblance to the Lazarus and Folkman definition. Of the studies that used a model of coping, three used the Transactional Theory of Stress and Coping and one used the Moos and Tsu model of the crisis of physical illness.

**Coping measures and domains**

Ten different coping measures were identified in the 14 studies reviewed, with some measures used in more than one study—for example, the WCQ. Table 2 presents an overview of the measures used, including the coping domains assessed by each of the coping measures, and the psychometric properties of each measure provided in the studies reviewed. The WCQ was the most commonly used of the coping measures and was used in five studies. The full 66-item WCQ, however, was used in only one study, with modified versions of the scale used in the remaining three studies reviewed. The next most used coping measure in the studies was the Freiburg Questionnaire on Coping with Illness, represented in three of the studies.

ment widely used in German-speaking countries, in comparison with the internationally used WCQ. Two condition-specific measures of coping were used in two studies. One study used a modified version of the Mental Adjustment to Cancer Scale and titled their version the Mental Adjustment to Stroke Scale. The second condition-specific measure was a revised version of the Ways of Coping—Cardiovascular Accident Scale. This revised version was called the Ways of Coping—Cardiovascular Accident Scale.

Coping strategies used after a stroke

Two studies reported greater use of active problem-oriented coping in patients with stroke than in other populations tested, whereas another study reported that patients with stroke used fewer active problem-oriented coping strategies than participants with other brain disorders. Findings on the use of problem-focused as opposed to emotion-focused strategies were conflicting. One study reported greater use of emotion-focused coping behaviours than problem-focused coping, whereas another study reported greater use of problem-focused coping strategies. Avoidance-type coping strategies were the least used in two of the studies. The four studies that examined the stability of coping over time found that the coping strategies used did not change markedly at the different time points assessed.

On the Mental Adjustment to Stroke Scale, “emotionalism” was found to correlate with helplessness or hopelessness and anxious preoccupation. However, the term “emotionalism” was not defined in the study that used this measure. Anxiety was associated with more frequent use of avoidant coping strategies, whereas patients with stroke who were depressed in comparison with patients with stroke who were not depressed used less behavioural action and fewer rational cognition strategies. Depression was associated with avoidant coping and was specifically associated with greater use of escape avoidance and use of magic thinking coping domains. Training of patients had no effect on coping behaviours on the condition-specific Ways of Coping—Cardiovascular Accident Scale. Physical ability was associated with coping effectiveness and coping behaviour in two studies. De Sepulveda and Chang reported that functional disability reduced coping effectiveness and Herrmann et al. found that the degree of motor impairment correlated with a depressive coping style. Less frequent use of finding meaning and more frequent use of avoidance coping were predictors of depression before discharge from rehabilitation.

Psychometric properties

Table 2 presents the psychometric properties of the coping scales. Internal consistency data were reported for coping subscales in seven studies. Therefore, in seven studies no psychometric data were reported. One study reported internal consistency values for the original WCQ measure and no data were identified for the modified version of the scale that was used. Where reported, Cronbach's α ranged from 0.41 to 0.90 (table 2). Only one coping measure (The Trier Scales on coping with illness) reported internal consistency reliabilities with Cronbach's α of 0.7 or higher for all subscales. Of note, test-retest reliabilities were identified by one study that reported moderate to high correlations of the Brief Religious Coping Scale's coping strategies over time.

The main type of validity data reported in nine studies was r values, with r values >0.8. The coping domains of information seeking and search for affiliation correlated highly with subjective well-being and autonomy, providing supporting evidence of the validity of this scale. Overall, there was little evidence of construct validity for the coping scales used in the studies reviewed, and the correlations between the subscales of the coping scales and other variables reported were generally weak.

DISCUSSION

The aim of this paper was to review quantitative coping research in populations of patients with stroke. Overall, a modest number of papers met the search criteria, highlighting the scarcity of quantitative research on the processes of coping and adaptation in the literature on stroke. Although over the past decade psychosocial aspects of recovery in stroke have begun to receive attention, much of the literature continues to focus on physical abilities. Not all studies reviewed had a full complement of patients with stroke, but included other vascular and cerebral diseases, making comparisons between studies complex and reducing the possibility of finding consistencies between studies. A further reason for the small number of studies identified in this review may result from reporting bias, in that only the studies with significant findings could have been published. In addition, given that the median sample size for patients with stroke reported in table 1 is 55, the values reported in the current review may be overestimates of the size of relationships between coping strategies and other variables. Routine reporting of confidence intervals for sample correlations would provide greater insight into the plausible range of correlation values and facilitate more definitive conclusions regarding the strength of the relationship between coping strategies and other variables.

Conceptual basis

This review discussed some of the major conceptual issues that exist in the literature with regard to coping measurement after stroke. These issues include the lack of consistent definitions throughout studies and the deficiency of coping theoretical frameworks. Eight of the studies defined what they meant by the term “coping”, with a consistent definition used in three of the studies. The conceptual shortcoming of inconsistent definitions shares some commonality with the general literature on coping. Only a small number of studies outlined a theoretical framework of coping, the one most often used being the Transactional Model. The conceptual shortcomings of inconsistent definitions shares some commonality with the general literature on coping. A large number of coping questionnaires, each proposing different dimensions, exists in the general literature on coping. This was reflected in the current review, where 10 different coping measures were used in the 14 studies reviewed. The heterogeneity of coping measures in the studies reviewed creates challenges for detecting trends or drawing conclusions regarding the use of coping strategies after stroke.

The conceptualisation of the structure of coping to date has been complex and varies in terms of measurement in different studies. A helpful development has been the hierarchical conceptualisation of Skinner et al, in which the structure of coping spans the conceptual space between instances of coping and adaptive processes. This hierarchy operates (from the bottom up) on four levels: (1) instances of coping (eg, “I wore my lucky t-shirt the day of the exam”); (2) ways of coping (eg, problem-solving, rumination, venting, escape); (3) dimensions of coping (eg, problem, emotion, avoidance-focused coping); and (4) strategy of adaptation
(ie, continuing to secure adequate information about the environment or escaping from a potentially dangerous transaction). This conceptualisation of the structure of coping organises the various coping items and domains identified by the various coping measures in the literature. It provides category systems for classifying ways of coping. This type of framework may prove useful when assessing coping with various different measures and should allow researchers on the subject of coping after stroke to come to some general consensus, as the levels within this framework provide a clearer categorisation of strategies.

**Coping measures, domains and strategies**

Little overlap was observed in the measures used in the studies included in this review, and the coping strategies used by patients with stroke varied across studies. Overall, it was not possible to identify conclusively the specific coping strategies used by people in either the acute phase after stroke (ie, within the first 6 months) or in the longer term (after 6 months). However, some general trends were reported. First, there were some recurrent findings. The use of approach and active problem-oriented coping strategies were reported more often than were emotion-focused coping strategies. However, the results did not indicate the coping strategies that were more or less effective in terms of outcome of stroke. In the general literature on coping, most negative life events seem to elicit both types of coping strategies, although people with more personal and environmental resources may rely more on approach and active problem-oriented coping and less on avoidance emotional coping. A longstanding issue in the perspective on individual differences is whether avoidant or emotional responses or problem-solving coping methods are superior. Avoidant responses may be more effective for managing short-term threats, but for long-term threats problem-solving coping may manage stress more effectively. It is therefore imperative to examine the coping process over longer durations in patients with stroke to determine the strategies consistently used in the long term. This review suggests that, in fact, strategies do not change over time; with considerable stability in use of coping strategies, longitudinal studies failed to detect significant changes over time (p<0.05). However, this apparent lack of change may simply reflect low levels of statistical power. Future research examining the stability of coping strategies over time could use latent growth analysis to explore this issue.

Combining the findings of this review—that is, that coping strategies adopted by patients in the acute phase after stroke are unlikely to change in the longer term, with research indicating higher levels of psychological distress in those using less active, problem-oriented coping strategies and more avoidance strategies, suggests that an intervention targeted at coping strategies typically associated with distress may improve patient recovery considerably. The general literature has shown similar findings in a variety of studies on diverse populations where emotion-oriented coping style has been positively linked, for both men and women, with negative health variables such as anxiety, depression and poor recovery from illness. Evidence on coping and recovery of physical function after stroke is generally lacking in the literature. Studies to date have focused on the relationship between physical function and depression. Further studies assessing depression and physical function should incorporate the coping process to identify if there is an important predictive relationship between variables. Furthermore, nearly half of the studies reviewed were of sample populations with brain disorders other than stroke. In some of these studies, no specific inferences could be made in relation to the type of coping strategies relevant to a population with stroke.

**Psychometric properties**

In most of the studies reviewed, psychometric properties of the coping measures used were under-reported or were not reported at all. The internal consistency reliabilities of the coping subscales, where reported, were generally less than the value considered acceptable (Cronbach’s α>0.7) and test–retest reliability was reported in only one of the studies reviewed. One study reported internal consistency coefficients from the original psychometric data of the coping measure and reported no data on the modified version of the scale used in the researchers’ own study. Specific concerns exist in the context of stroke, such as stroke sequela—for example, cognitive, language or visual deficits—that may affect reliable measurement in a population with stroke. Of note, only one study described a cognitive screening method. Many generic measures of coping may be less applicable in a population coping with health problems. Hence, many researchers who use scales such as the WCC or the WCQ have modified the instruments when studying medical populations by dropping or adding items, or by changing the scoring system. Although these modified scales may remove some of the problems associated with inapplicable items, according to Parker and Endler, new inadequacies are produced. These include difficulty with generalising results from one sample or health problem to another and frequent poor reporting of psychometric data on these modified scales. In terms of validity, only one category was represented in the results—that is, correlations of coping subscales with other specified variables (construct validity). This finding is in keeping with that of Hogan and Agenello. In an investigation on current research practice regarding reporting measurement validity evidence, only 55% of research reports included any type of validity evidence, and on those reporting validity information, most reported correlations with other variables. The Behavioral Subscales of the Trier Scales on coping with illness showed very strong correlations (r = 0.83–0.97) with well-being. However, in general, the correlations between coping subscales and other specified variables reported in table 2 are weak (eg, r = 0.2) to moderate (eg, r = 0.5). These methodological limitations, such as the conceptual issues discussed earlier, are similar to deficiencies identified in the general literature on coping. Researchers in the field of coping have described in detail the conceptual and methodological difficulties regarding the measurement of coping.

**Further directions and conclusions**

Literature on measuring coping quantitatively in a population with stroke remains scarce, allowing both researchers and clinicians to draw few inferences on the type of coping strategies people actually use in both the acute and chronic stages after stroke. No unique coping strategies are used at different time points across the adaptive recovery period, but coping strategies seem to remain consistent over time. This is supportive of a dispositional approach, which assumes that people bring to a given context a relatively stable coping “disposition” that is minimally influenced by situational contingencies. Most coping measures used in the studies reviewed have one or more psychometric limitations—for example, weak correlations with other variables or inadequate psychometric reporting of the measures used in the studies and a failure to account for difficulties with measuring due to stroke sequelae, such as communication difficulties or cognitive impairment.

Considerable potential exists for further investigation on this topic, but it is imperative for authors to state their definition and framework of coping. The limited number of
follow-up studies on stroke should encourage more longitudi-nal studies assessing coping over time, with particular attention to assessment of coping within the initial acute phase of stroke—that is, within the first month—as a marker to determine what people are likely to use in the long term. It remains to be clarified whether maladaptive strategies can be identified by examining associated variables such as quality of life, mood and level of disability—for example, what the patient is able to do for himself or herself outside the clinical setting. Lazarus' suggested that within-subject prospective longitudinal research is required to measure coping, as this allows researchers to identify psychological structures such as stable personality dispositions and changes (or processes) in psychological reactions over time and diverse conditions.

From this review, there are no inferences that can be made on the type of coping strategies used in a population with stroke. Further studies are required that consistently use coping measures with similar coping domains to ensure identification of broadly successful and unsuccessful strategies in the context of stroke. Consideration and specification of adaptation models relevant to the adaptation process after stroke will further improve the use of findings from research studies on coping and adaptation after stroke.
