Mandelic acid derived ionic liquids: synthesis, toxicity and biodegradability†

Hannah Prydderch,^a Annette Haiß,^b Marcel Spulak,^c Brid Quilty,^d Klaus Kümmerer,^b Andreas Heise^e and Nicholas Gathergood^{*f}

A series of ten ionic liquids (ILs) was synthesised from the renewable resource mandelic acid. The ILs showed low antimicrobial activity towards the thirteen bacterial and twelve fungal strains they were screened against. A general trend of increasing bacterial toxicity in the order methyl ester < ethyl ester < *n*-butyl ester/amide was observed. IL biodegradability was evaluated using the Closed Bottle test (OECD 301D). Biodegradation increased in the order of increasing alkyl chain length for the ester ILs (methyl < ethyl < *n*-butyl). Despite none of the ILs presenting as readily biodegradable (>60% in 28 days), a series of biodegradation transformation products has been proposed based on the degradation of the ester/amide alkyl chain. This data has allowed for an assessment of the effect of IL structural features on toxicity and biodegradation, particularly allowing for a comparison to earlier work where additional oxygen atoms were present to facilitate biodegradation and attenuate toxicity. The mandelic acid derived ILs did not pass the Closed Bottle test (OECD 301D) and can be included in the rules of thumb for the design of biodegradable ILs.

Introduction

Ionic liquids (ILs) are poorly coordinated salts most often with melting points <100 °C.¹ The myriad of properties that ILs can possess (such as highly tuneable, low vapour pressure, large liquid range, low flammability and high solvating capacity) often makes them attractive as reaction additives and alternative solvents for the replacement of volatile organic compounds.² However, possession of these properties does not necessarily make them a greener alternative. An important consideration is the toxicity and biodegradability assessment of chemicals,³ which can lead to the design of safer (low toxicity and high biodegradability, *i.e.* complete mineralisation) ILs.

There have been numerous efforts towards this aim with several works on the biodegradability and toxicity of ILs published since the early 2000's.^{4–16}

The utilisation of renewable resources for the synthesis of ILs has also been of great interest towards the aim of creating more sustainable ILs. Examples in the literature include the use of cholinium,^{17,18} prolinatate,¹⁹ L-lactate²⁰ and succinate,²⁰ where low toxicity and readily biodegradable ILs from renewable resources have been identified.¹⁷ More recently renewable pyridinium ILs have been synthesised from pyridinium zwitterions derived from amino acids and furfural.²¹

Mandelic acid is an aromatic α -hydroxy acid that is found naturally in small quantities in plant tissues such as wheat leaves and grapes.²² A wide range of organisms (*e.g.* *Penicillium chrysogenum*²³ and phytoplankton²⁴) can convert the naturally occurring compounds L-phenylalanine and phenyl acetic acid into mandelic acid.²² Mandelic acid can also be obtained by heating the glycoside amygdalin with concentrated hydrochloric acid.²⁵ Amygdalin can be isolated from the seeds of the bitter almond tree^{26,27} and is also found in apricots^{27,28} and peach pits.²² In industry mandelic acid is made from the acid or enzyme catalysed hydrolysis of mandelonitrile.²⁹ However, as mandelonitrile is often produced from the reaction between benzaldehyde and sodium cyanide, alternative methods avoiding the use of this toxic reagent to prepare mandelic acid and its derivatives have been developed.³⁰ Optically pure (*R*-) and (*S*-)mandelic acid have also been produced from the renewable feedstock glucose using a genetically modified strain of *E. coli*.³¹

† Electronic supplementary information (ESI) available: Includes additional antimicrobial screening results, experimental procedures for the synthesis of ILs and reaction intermediates with characterization data (NMR, IR, mp, MS), as well as a description of the antimicrobial and biodegradation screening methods. See DOI: 10.1039/c6ra25562k

Studies on the toxicity of ILs that contain phenyl rings as an alternative to long alkyl chains have shown that it is possible to incorporate a lipophilic substructure into an IL whilst still maintaining low levels of toxicity.^{32,33} Coleman *et al.*³⁴ and more recently Jordan *et al.*³⁵ additionally showed that the introduction of a phenyl group in the form of phenylalanine in IL structures did not result in high levels of antimicrobial activity towards the bacterial or fungal strains screened, in the majority of cases. The impact of phenyl substitution was assessed in terms of IL cytotoxicity by Ranke *et al.* in 2007.³³ Here the authors studied the influence of cation lipophilicity on IL cytotoxicity in IPC-81 leukemia cells and determined that lipophilicity was a dominating factor for IL cytotoxicity. Relatively low toxicity of the phenyl IL 1-methyl-3-(phenylmethyl)-imidazolium chloride was demonstrated ($EC_{50} > 1000 \mu\text{M}$) compared to the 1-heptyl-3-methyl-1*H*-imidazolium chloride (same number of carbons in cation side chain as the phenyl IL) ($EC_{50} = 399 \mu\text{M}$). The decrease in toxicity was attributed to the decrease in IL lipophilicity due to the presence of the phenyl group compared to the heptyl side chain. This result demonstrates that it is possible to attenuate IL cytotoxicity by replacing alkyl chains (*e.g.* heptyl) with phenyl groups. Ranke *et al.* also reported that decreasing the IL alkyl chain length from heptyl to *n*-butyl resulted in lower cytotoxicity (*e.g.* 1-butyl-3-methyl-1*H*-imidazolium chloride, $EC_{50} = 3548 \mu\text{M}$).

The introduction of aromatic rings can however have a marked effect on compound biodegradability (as determined from biodegradation in CO_2 Headspace test ISO 14593), as in the case of Gore *et al.* where the introduction of benzyl groups significantly reduced IL biodegradability.³⁶ In 2012 Coleman *et al.* showed that amino acid ILs containing phenyl rings can present as readily biodegradable.³⁴ The assumption was that the aromatic ring of the phenylalanine moiety was converted to CO_2 , although no transformation product analysis was performed in that study to confirm this breakdown. More recently Jordan *et al.*³⁵ and Haiß *et al.*³⁷ have further shown that a fully mineralisable IL can be produced from an amino acid (phenylalanine) IL containing an aromatic side chain. Although, the introduction of a phenyl group in the form of phenylalanine did not lead to a significant increase in biodegradation in all cases. This demonstrates the challenge of identifying “rules of thumb”³⁸ to assist in the design of biodegradable ILs.^{12,13}

Previous work in the Gathergood group includes the design and synthesis of low toxicity ILs from mandelic acid derivatives.³² Herein we present a novel series of ILs synthesised directly from the renewable building block mandelic acid in a shorter and more efficient synthesis. Mandelic acid was selected as the backbone for the synthesis of the ILs as there are numerous reports in the literature detailing the microbial metabolic pathways for the degradation of mandelic acid and mandelates.^{22,39–42} Thus, by utilising a structural moiety susceptible to microbial breakdown we aim to better understand the ready biodegradability of the ILs.

It is desired that the ILs reported in the study will present with low toxicity similar to the previous class of mandelic acid derived ILs.³² By carrying out toxicity screening under the same

conditions to the previously published work, a direct comparison of IL toxicity between the two series was possible. The study presented herein additionally expands on the previous work by providing an evaluation of the biodegradability of the newly synthesised ILs. Overall, this study aims to further investigate the effect of structural modifications on IL toxicity and biodegradation, in particular the effect on toxicity of removing oxygen from the previous class of ILs. This work intends to satisfy the 4th, 7th and 10th principles of green chemistry: designing safer chemicals, the use of renewable feedstocks, and designing for degradation (respectively).

Results and discussion

Synthesis

A series of ten mandelic acid derived ILs (**1–10**) was synthesised with specifically designed structural motifs to allow for the investigation of their effect on toxicity and biodegradation (Fig. 1). These structural features included: three alkyl chain lengths, *n*-butyl, ethyl and methyl; both ester and amide moieties; the halide anion bromide; and various N-heterocyclic headgroups, 1-methylimidazolium, pyridinium, 3-methoxy pyridinium and 3-(ethoxycarbonyl)pyridinium.

Other than the research carried out on this particular class of compounds directly preceding this work,³² there have been several mentions of this class of compounds in the literature.^{43–45} However, the only exact compound match for this new series that could be found in the literature was for the pyridinium ethyl ester IL (**4**), where compound characterisation could be found, but not biodegradation and toxicity analysis.⁴⁶

All the ILs were synthesised as the racemate from the starting material *DL*-mandelic acid as both the *D*(–) and *L*(+) isomers are known to occur in nature.⁴² The synthesis of the ILs consisted of three steps (Schemes 1 and 2): esterification or amidation of mandelic acid; halogenation of the α -position of the ester/amide with thionyl bromide; and nucleophilic substitution of

Fig. 1 Mandelic acid derived bromide ILs (**1–10**).

Scheme 1 General synthesis of mandelic acid derived ester ILs (1–8).

Scheme 2 General synthesis of mandelic acid derived amide ILs (9 and 10).

the α -halo ester with an aromatic N-heterocycle. The synthesis of the previously reported mandelic acid derived ILs required an additional synthetic step to produce the IL starting materials, as they were not synthesised directly from mandelic acid.³² Thus, the ILs described herein (1–10) were produced in a shorter and more efficient synthesis directly from the renewable resource. Additionally, mandelic acid production from benzaldehyde using sodium cyanide is avoided in this route by utilising the natural mandelate.³⁰

Esterification of mandelic acid was carried out by the well-known Fischer–Speier method⁴⁷ to produce methyl, ethyl and *n*-butyl mandelic acid esters **11–13** (Scheme 1) in excellent yields (92–97%). Modified literature procedures were employed for the synthesis of previously reported methyl ester **11**⁴⁸ and ethyl ester **12**,⁴⁹ with a new procedure described for the synthesis of *n*-butyl ester **13**⁵⁰ (see ESI†). The *n*-butyl amide **14** (Scheme 2) was synthesised with acetyl chloride (AcCl), according to a modified version of the literature procedure,⁵¹ in high yield (89%) (see ESI†). Initial attempts to synthesise **14** by greener methods did not proceed in high yields (<9%).^{52,53}

Synthesis of the α -bromoester and α -bromoamide alkylating agents **15–18** (Schemes 1 and 2) were carried out by addition of

thionyl bromide (SOBr_2) to the mandelic acid esters **11–13** and amide **14**. The reaction occurs *via* a *meso* substitution of the alcohol by bromine and was utilised to give alkylating agents **15–18** (Schemes 1 and 2) in moderate yields (51–67%). Previously reported α -bromoester **15** was synthesised by a modification of the literature procedure,⁵⁴ with a new procedure described for α -bromoester **16**⁵⁵ (see ESI†).

ILs **1–10** (Schemes 1 and 2) were synthesised *via* a nucleophilic substitution reaction between an N-heterocycle and the α -bromoester/ α -bromoamide of mandelic acid (**15–18**) (see ESI†). N-heterocycles 1-methylimidazole, pyridine, 3-methoxy pyridine and ethyl nicotinate (required for the 3-(ethoxycarbonyl)pyridinium headgroup) were selected for the IL synthesis. Previously reported IL **4**⁴⁶ was prepared according to a new synthetic procedure (see ESI†).

Seven of the ILs (**1–5**, **9** and **10**) were produced in excellent yields (84–99%), with the three *n*-butyl esters with pyridinium (**6**), 3-methoxy pyridinium (**7**) and 3-(ethoxycarbonyl)pyridinium (**8**) headgroups produced in moderate yields (56, 74 and 63% respectively). All ten ILs were obtained as crystalline solids with a wide range of melting points observed (48–169 °C) (see ESI†). At the COIL-6 conference in South Korea, Professor Kenneth

^a CA1: *Candida albicans* ATCC 44859, CA2: *Candida albicans* ATCC 90028, CP: *Candida parapsilosis* ATCC 22019, CK1: *Candida krusei* ATCC 6258, CK2: *Candida krusei* E28, CT: *Candida tropicalis* 156, CG: *Candida glabrata* 20/I, CL: *Candida lusitanae* 2446/I, TA: *Trichosporon asahii* 1188, AF: *Aspergillus fumigatus* 231, AC: *Absidia corymbifera* 272, TM: *Trichophyton mentagrophytes* 445. ^b IC₅₀ values were assessed for AF, AC and TM and IC₈₀ for all other strains.

Seddon proposed that the arbitrary use of 100 °C as a melting point cut-off for the definition of an IL was inflexible and constraining and should no longer be used as a prerequisite for classification as an IL.⁵⁶ Thus, the terminology of IL is used herein despite the majority of the ILs described possessing melting points >100 °C. ILs 1 and 6 had the lowest melting points (61–63 and 48–50 °C respectively) despite any similar structural features. The highest melting points for the series were observed for the pyridinium ILs 4 and 10 (161–162 and 167–169 °C respectively). ILs 2 and 9 had melting points around 140 °C (140–142 and 143–145 °C respectively), again with no similar structural features. ILs 3 and 5 had melting points around 100 °C (101–102 and 99–101 °C respectively), both with 1-methylimidazolium headgroups. ILs 7 and 8 had moderately high melting points (127–128 and 112–113 °C respectively), both *n*-butyl esters with 3-methoxy pyridinium and 3-(ethoxycarbonyl)pyridinium headgroups respectively. It is observed that the class of headgroup has a more marked effect on the IL melting points than the alkyl chain length. In all but one case the pyridinium ILs had higher melting points than the 1-methylimidazolium ILs with the same ester/amide alkyl chain, with this trend only reversed for the *n*-butyl ester ILs 5 and 6. The *n*-butyl amides ILs 9 and 10 had higher melting points than

the *n*-butyl ester ILs, which is expected due to their additional hydrogen bond donor ability.

Microbial toxicity screening

Our strategy regarding toxicity screening of chemicals as part of a tandem toxicity and biodegradation assessment has been previously published.^{34–37} One reason a compound can fail a biodegradation test is due to high toxicity to critical microorganisms in the inoculum required for breakdown. For instance, previous studies have shown that high toxicity to bacteria, e.g. *Pseudomonas putida*, can be linked to inhibited biodegradation.⁵⁷ Thus, completing a microbial toxicity study prior to biodegradation screening provides valuable data to assist analysis of biodegradation results. Compounds are first evaluated against twenty bacterial and fungal strains to identify high antimicrobial activity examples. Secondly, IC₅₀ values at higher IL concentrations are measured for compounds which do not exhibit high antimicrobial activity. Compounds which have high antimicrobial activity are identified as ‘hit’ compounds as part of our group’s medicinal chemistry and biocide research interests. Low antimicrobial activity compounds are prioritised for green chemistry applications.

Fungal toxicity results

The *in vitro* antifungal activities of ILs 1–10 (Table 1) were evaluated against four ATCC strains (*Candida albicans* ATCC 44859, *Candida albicans* ATCC 90028, *Candida parapsilosis* ATCC 22019, *Candida krusei* ATCC 6258) and eight clinical isolates of fungi, five yeasts (*Candida krusei* E28, *Candida tropicalis* 156, *Candida glabrata* 20/I, *Candida lusitanae* 2446/I, *Trichosporon asahii* 1188) and three filamentous fungi (*Aspergillus fumigatus* 231, *Absidia corymbifera* 272, *Trichophyton mentagrophytes* 445). Three ATCC strains were also used as the quality control strains. All the isolates were maintained on Sabouraud dextrose agar prior to being tested. Minimum inhibitory concentrations (MICs) were determined by modified CLSI standard of the microdilution format of the M27-A3⁵⁸ and M38-A2⁵⁹ documents for yeasts and filamentous fungi respectively. MIC values were calculated after 72 and 120 h for *T. mentagrophytes*, and for all other strains MIC values were calculated after 24 and 48 h. The MICs were defined as 50% inhibition (IC₅₀) of the control growth for yeasts or 80% inhibition (IC₈₀) of the control growth for filamentous fungi. The maximum test concentration of the IL was dependant on the IL aqueous solubility, with the highest IL concentration in the test being 2.0 mM. See ESI† for full experimental details.

The results from Table 1 show that the 1-methylimidazolium methyl ester IL (1), the 3-(ethoxycarbonyl)pyridinium *n*-butyl ester IL (8) and the 1-methylimidazolium and pyridinium *n*-butyl amide ILs (9 and 10) did not have high fungal toxicity, up to the maximum IL concentration limit, with IC₅₀/IC₈₀ values >2.0 mM. The pyridinium methyl and ethyl ester ILs (2 and 4) and the 3-methoxy pyridinium *n*-butyl ester IL (7) did not have high toxicity, up to the maximum IL concentration limit, with IC₅₀/IC₈₀ values >1.0 mM. The 1-methylimidazolium and pyridinium *n*-butyl ester ILs (5 and 6) inhibited *C. tropicalis* at

Fig. 2 Mandelic acid derived ILs 19–20.³²

2.0 mM after 24 h but showed no inhibition up to the test concentration of 2.0 mM after 48 h, suggesting that the fungal strain was able to overcome the initial observed inhibition at 2.0 mM after 24 h and recover. However, this result is not significant when compared to other data in Table 1, especially as it appears for only one fungal strain. The concentration is also well above the level used in the biodegradation studies. The overall findings are that none of the ILs demonstrated high toxicity to the range of fungal strains screened against. The 1-methylimidazolium ethyl ester IL (3) inhibited *C. krusei* ATCC 6258 at 0.50 mM after both 24 and 48 h, and *C. krusei* E28 at 1.0 mM after both 24 and 48 h. Higher levels of fungal toxicity are usually observed as the length of the alkyl chain increases.⁷ Although it is unexpected that the ethyl ester IL (3) is more toxic than the *n*-butyl analogue (5), one must be careful not to over-interpret the data based on two compounds. High toxicity was not observed for the mandelic acid derived ILs (1–10) in this screening, which is a significant result for the design of safer ILs. As no compounds with high fungal toxicity were found, all were classed as suitable substrates for biodegradation screening based on fungal toxicity data.

Previous work evaluated the antifungal activity of a series of mandelic acid derived ILs similar to those described herein, but which incorporated a higher oxygen content (*e.g.* ether, phenol and catechol groups are present).^{60,61} When comparing the IC₈₀ or IC₅₀ values of the 1-methylimidazolium and pyridinium methyl and *n*-butyl ester ILs (1, 2, 5 and 6) (Table 1) to the mandelic acid derived ILs previously published with the same ester alkyl chain length and headgroup³² (19–22) (Fig. 2), only IL 1 had the same low level of inhibition as the previous ILs (19–22) with no high toxicity up to the maximum IL concentration limit (IC₅₀/IC₈₀ > 2.0 mM)^{60,61} (Table S1†). This result is not surprising as a lower level of inhibition is expected for the previous ILs (19–22) due to the presence of the oxygen functionality on the aromatic ring which decreases IL lipophilicity, increases IL hydrophilicity, and in turn decreases IL toxicity.⁶² However, despite a higher fungal toxicity observed for the new ILs (1, 2, 5 and 6) the results herein do not represent a large increase in the level of inhibition compared to the previously published ILs (19–22). IL 19 has been included here for

comparative purposes despite containing a chloride anion, as the halide anions bromide and chloride have previously been reported to have similar toxic effects in imidazolium ILs.⁶³

Bacterial toxicity results

The *in vitro* antibacterial activities of ILs 1–10 (Table 2) were evaluated against three ATCC strains (*Staphylococcus aureus* ATCC 6538, *Escherichia coli* ATCC 8739, *Pseudomonas aeruginosa* ATCC 9027) and five clinical isolates (*Staphylococcus aureus* MRSA HK5996/08, *Staphylococcus epidermidis* HK6966/08, *Enterococcus* sp. HK14365/08, *Klebsiella pneumoniae* HK11750/08, *Klebsiella pneumoniae* ESBP HK14368/08). The ATCC strains were also used as the quality control strains. MIC values were calculated after 24 and 48 h. The MICs were defined as 95% inhibition (IC₉₅) of the control growth. The maximum test concentration of the IL was dependant on the IL aqueous solubility, with the highest IL concentration in the test being 2.0 mM. All the isolates were maintained on Mueller–Hinton dextrose agar prior to being tested. See ESI† for full experimental details.

The results from Table 2 show that the ILs 1, 2, 4 and 7–10 did not have high toxicity towards the bacterial strains screened against. The pyridinium ethyl ester IL (4) and the 3-methoxy pyridinium *n*-butyl ester (7) did not have high toxicity, up to the IL maximum concentration limit, with IC₉₅ values >1.0 mM. The 1-methylimidazolium *n*-butyl amide IL (9) did not have high toxicity, up to the IL maximum concentration limit, with IC₉₅ values >2.0 mM. The 1-methylimidazolium and pyridinium methyl ester ILs (1 and 2), the 3-methoxy pyridinium *n*-butyl ester IL (8) and the pyridinium *n*-butyl amide IL (10) all inhibited *S. epidermidis* at a concentration of 2.0 mM, with IL 10

additionally inhibiting *S. aureus* at 2.0 mM and IL 1 additionally inhibiting *S. aureus* and *K. pneumoniae* ESBL at 2.0 mM. Overall, the results for ILs 1, 2 and 8–10 are not significantly different. The 1-methylimidazolium *n*-butyl ester IL (5) inhibited *S. aureus* and *S. epidermidis* at 2.0 mM and *K. pneumoniae* ESBL at 1.0 mM after 24 h, but after 48 h no longer inhibited *S. aureus*, *S. epidermidis* and *K. pneumoniae* ESBL up to the test concentration of 2.0 mM, suggesting that the bacterial strains were able to overcome the initial observed inhibition after 24 h and recover. The pyridinium *n*-butyl ester IL (6) inhibited *S. aureus* MRSA at 2.0 mM after 24 h, but after 48 h no longer inhibited *S. aureus* MRSA up to the test concentration of 2.0 mM. IL 6 also inhibited *S. aureus* and *S. epidermidis* at 0.50 mM after 24 h, which reduced to inhibition at 2.0 mM to *S. aureus* and 1.0 mM to *S. epidermidis* after 48 h. The 1-methylimidazolium ethyl ester IL (3) showed the greatest level of inhibition to the bacterial strains across the board with the highest level of inhibition observed against *S. epidermidis* (IC₉₅ = 0.25 mM) and against *S. aureus*, *S. aureus* MRSA and *Enterococcus* sp. (IC₉₅ = 0.50 mM). ILs 3 and 6 generally showed greater inhibition towards the Gram-positive bacterial strains (*S. aureus*, *S. aureus* MRSA, *S. epidermidis* and *Enterococcus* sp.) than towards the Gram-negative bacterial strains (*E. coli*, *K. pneumoniae*, *K. pneumoniae* ESBL and *P. aeruginosa*). This observation is most pronounced for IL 3, where the greatest level of inhibition of a Gram-negative bacterial strain was observed against *K. pneumoniae* ESBL (IC₉₅ = 0.50 mM). The greatest level of inhibition by IL 3 for a Gram-positive bacterial strain was observed against *S. epidermidis* (IC₉₅ = 0.25 mM); however, this is a much higher concentration than used in the biodegradation testing (CBT). The overall findings of this work show that none of the ILs demonstrated high toxicity to the range of bacterial strains screened. IL 3 presented with the highest toxicity; however, this was still only observed as moderate toxicity against several bacterial strains.

In all cases the previously synthesised mandelic acid derived ILs³² (19–22) (Fig. 2) had lower levels of inhibition than the new ILs with the same ester alkyl chain length and headgroup (1, 2, 5 and 6) for every bacterial strain that was screened against, with no high toxicity observed up to the maximum IL concentration limit (IC₉₅ values > 2.0 mM) (Table S2†).^{60,61} Despite a higher bacterial toxicity observed for the new ILs (1, 2, 5 and 6), the results presented herein (IC₉₅ values in the range 0.50–2.0 mM) do not represent a large increase in the level of inhibition. This is a significant positive result considering the new class of ILs are synthesised directly from a renewable resource in a shorter and more efficient synthesis.

The antibacterial activities of ILs 1–10 were also evaluated against one Gram-positive bacterial strain (*Bacillus subtilis* DSMZ 10) and four Gram-negative bacteria (*Escherichia coli* DSMZ 498, *Pseudomonas fluorescens* DSMZ 50090, *Pseudomonas putida* CP1, and *Pseudomonas putida* KT 2440). Of note, the *Pseudomonas* strains have been reported as important for biodegradation.^{57,64} The bacterial toxicity of the ILs was determined by bacterial growth inhibition in a 24 hour assay and are expressed as IC₅₀ values. Stock solutions of the ILs were prepared in deionised water to a maximum concentration of 2000 mM. The concentration of each stock solution was determined by the maximum aqueous solubility of each IL (Table S3†). ILs 2, 4, 7 and 9 had a solubility limit lower than 2000 mM. The maximum test concentration of each IL was a factor of 10 dilution of the IL stock solution. All the toxicity tests were carried out in triplicate. See ESI† for full experimental details.

The results from Table 3 show that the majority of the ILs have low toxicity (IC₅₀ values > 25–50 mM) towards the bacterial strains screened against, with the lowest toxicity observed for the pyridinium ethyl ester IL (4) against *P. putida* KT 2440 (IC₅₀ > 100 mM). The highest levels of inhibition were observed for the 1-methylimidazolium *n*-butyl ester IL (5) which inhibited *E. coli* and *P. putida* CP1 with IC₅₀ values of 6.25–12.5 mM, the *n*-butyl

amide pyridinium IL (10) which inhibited *E. coli* and *P. fluorescens* with IC_{50} values of 6.25–12.5 mM, and the 1-methylimidazolium *n*-butyl amide (9) which inhibited *E. coli* with IC_{50} values of 6.25–12.5 mM. A general trend of increasing IL toxicity with increasing alkyl chain length was observed across all bacterial strains in the order methyl ester < ethyl ester < *n*-butyl ester/amide. In general the methyl ester ILs 1 and 2 had lower toxicity (IC_{50} = 25–200 mM) than the ethyl ester ILs 3 and 4 (IC_{50} = 25–100 mM), which in turn had lower toxicity than the *n*-butyl ester/amide ILs 5–8 (IC_{50} = 6.25–50 mM). This observed trend is expected as the literature shows increasing the length of alkyl groups of ILs leads to higher antimicrobial activity.⁷ This is also consistent with microbial toxicity data for linear alkylbenzene sulfonates and quaternary ammonium compounds.^{65,66} ILs with longer alkyl chains have a higher lipophilicity, which increases their ability to derange/interact or permeate through the bacterial cell membrane and disrupt it leading ultimately to cell death.^{62,67} IL 3 did not present with the same inhibition towards *E. coli* (IC_{50} = 25–50 mM) as observed in the previous bacterial toxicity run (IC_{95} = 2 mM) (Table 2), which is attributed to two different strains of *E. coli* used. There was no observed trend for the level of bacterial inhibition between 1-methylimidazolium ILs and pyridinium ILs across the various alkyl chain lengths. When comparing the IC_{50} values of the *n*-butyl ester ILs with pyridinium (6), 3-methoxy pyridinium (7) and 3-(ethoxycarbonyl)pyridinium (8) headgroups, a difference in the inhibition was only observed for IL 7, which showed the same increase in inhibition towards *B. subtilis* and *P. fluorescens* (IC_{50} = 12.5–25 mM). When comparing the inhibition of the Gram-positive bacteria *E. coli* with the Gram-negative bacteria *B. subtilis*, seven ILs (3–6 and 8–10) inhibited *E. coli* to a greater extent than *B. subtilis*. The remaining ILs (1, 2 and 7) inhibited both *E. coli* and *B. subtilis* to the same extent. High susceptibility of Gram-positive bacteria over Gram-negative bacteria has previously been highlighted in the literature and has been linked to IL lipophilicity.¹⁶

When comparing the IC_{50} values of the 1-methylimidazolium and pyridinium methyl and *n*-butyl ester ILs (1, 2, 5 and 6) to the mandelic acid derived ILs previously published with the same ester alkyl chain length and headgroup³² (19–22) (Fig. 2 and Table 3), in all cases the previous class of ILs had

lower levels of inhibition towards each bacterial strain that was screened against. Despite the maximum inhibition for the previous class being lower than the new class (highest toxicity, IC_{50} = 25–50 mM for IL 22 across all bacterial strains), it is a significant positive result that the new class of ILs do not represent a large increase in the level of inhibition (highest toxicity, IC_{50} = 6.25–12.5 mM for IL 5, 10 and 9 to several bacterial strains).

The microbial toxicity of the mandelic acid derived ILs 1–10 is clearly influenced by the lipophilicity of the IL structures. An increase in microbial toxicity over the previous class of mandelic acid derived ILs (19–22) is observed due to the removal of the phenyl ring substitution and subsequent increase in IL lipophilicity. It has been shown in the literature that decreasing the lipophilicity of imidazolium ILs by introducing ether groups into alkyl side chains can reduce IL microbial toxicity.⁶⁸ In an effort to decrease the microbial toxicity of the mandelic acid derived ILs 1–10, the replacement of the alkyl side chains with ethereal side chains was considered. However, as it is recommended that both methoxy- and ethoxy-terminal substitution are avoided with the aim of preventing any concurrent decrease

Fig. 3 Percentage biodegradation results for pyridinium ILs with benzyl (23) and methyl (24) analogues synthesised by Gore *et al.*³⁶ and the PTPs (23 PTP and 24 PTP). Biodegradation values assessed by the CO₂ Headspace test ISO 14593.

Fig. 4 Percentage biodegradation results for pyridinium ILs (25 and 26) synthesised by Coleman *et al.*³⁴ Biodegradation values assessed by the CO₂ Headspace test ISO 14593.

in IL biodegradability,⁶⁸ those ether derivatives were not selected as target ILs for this study.

The increase in IL toxicity that is observed with increasing alkyl chain length of the IL cation has been widely published.^{7,10,11,15,16,69,70} This observation presented for the mandelic acid derived ILs 1–10, where IL toxicity increased in the order methyl ester < ethyl ester < *n*-butyl ester/amide. Again, this is linked to an increase in IL lipophilicity where ILs with longer alkyl chain lengths have a higher lipophilicity and a greater interaction with cell membranes.

A quantitative structure–property relationship (QSPR) assessment carried out by Couling *et al.* for the marine bacteria *Vibrio fischeri* suggested that imidazolium ILs are more toxic than pyridinium ILs.⁶⁹ They propose this is due to an increased number of nitrogen atoms with two aromatic and one single bond in the imidazolium ring. However, in the work presented herein no clear conclusion could be drawn on the effect of the imidazolium and pyridinium headgroups on the microbial toxicity of the mandelic acid derived ILs 1–10.

Biodegradation studies

The aerobic biodegradability of the ten mandelic acid derived ILs 1–10 (biodegradation data, Table 4) were evaluated based on the Closed Bottle test (CBT) (OECD 301D) (see ESI† for method).⁷¹ This test is the most stringent of the OECD series as it works with the lowest density and functional diversity of bacteria. It was selected to make sure that any compounds which are classified as readily biodegradable are biodegraded everywhere in the aquatic environment. The validity of the test run was confirmed by satisfying the criteria for validity according to the test guidelines, which includes the reference substance sodium acetate reaching >60% biodegradation within 14 days and the concentration of oxygen in the bottles not decreasing below 0.5 mg L⁻¹ at any time.

A percentage of theoretical ester/amide biodegradation can be calculated for a compound by assuming that all the ester/amide carbons in the molecule are completely mineralised, *i.e.* broken down to carbon dioxide and water during biodegradation (oxidation of nitrogen by nitrification has to also be taken into account when calculating theoretical values of oxygen demand). The calculated theoretical ester/amide biodegradation values can then be compared to the experimental biodegradation values. If the values are similar it is reasonable to assume that biodegradation of the compound is probably occurring at the ester/amide. Significantly lower theoretical values than the experimental ones would suggest that other parts of the molecule are also likely to be biodegrading. Theoretical values that are significantly higher than the experimental values would suggest the ester/amide bond is likely not biodegrading, or only partially biodegrading. The theoretical ester/amide biodegradation calculations for ILs 1–10 were performed and the values were compared to the experimental results obtained in the CBT (Table 4).

Biodegradation screening results

The results show that none of the ILs reached >60% biodegradation in 28 days and thus cannot be classified as readily biodegradable by the OECD 301D CBT (Table 4). The 3-(ethoxycarbonyl)pyridinium *n*-butyl ester IL (8) had the highest level of biodegradation (31% in 28 days). The 1-methylimidazolium *n*-butyl amide IL (9) and pyridinium *n*-butyl amide IL (10) did not biodegrade at all under the test conditions (0–1% in 28 days). The percentage biodegradation reached by each IL in the test

Fig. 7 Structures of the PTPs for ILs 1–8 (31–34).

can be rationalised as biodegradation of the ester/amide groups (side chain) of the ILs. It is well known that ester groups can facilitate high levels of biodegradability and are often introduced into compounds to increase their levels of biodegradability,^{68,72} although there are some exceptions.³⁵ IL 8 contains the largest percentage of ester groups per molecule, with both an ethyl and *n*-butyl ester, thus it is not surprising that it shows the highest level of biodegradation in the CBT. The CBT results also show, as expected, that the level of biodegradation increased as the ester chain length increased. This trend is observed for the 1-methylimidazolium ILs 1, 3 and 5 (5, 20, 27% biodegradation in 28 days, for methyl, ethyl and *n*-butyl esters respectively) and the pyridinium ILs 2, 4 and 6 (8, 16, 21% biodegradation in 28 days, for methyl, ethyl and *n*-butyl esters respectively). Amide moieties have been shown in the literature to have poor levels of biodegradation,^{12,13,68} thus the low levels of biodegradation observed for the 1-methylimidazolium (9) and a pyridinium (10) *n*-butyl amide ILs in the CBT (0 and 1% biodegradation in 28 days, respectively) are expected. The CBT results of the *n*-butyl ester ILs 5–8 were in the range 21–31%. This narrow range of values does not support a detailed analysis of the effect of the headgroup (pyridinium, 3-methoxy pyridinium, 1-methylimidazolium and 3-(ethoxycarbonyl)pyridinium) on biodegradation.

This class of compounds (1–10) presents with low levels of biodegradation similar to the benzylimidazolium ILs previously reported by Gore *et al.*³⁶ Benzylimidazolium ILs containing amide groups showed very low levels of biodegradation (0–4%), a similar result to the amide ILs 9 and 10 reported herein. Biodegradation of a benzylpyridinium IL was also shown to increase with the introduction of an ethyl ester group (by 23%), a result which was also observed in this study for IL 8. A lower

level of biodegradation (CO₂ Headspace test ISO 14593) was published by Gore *et al.* for the benzylimidazolium IL 23 (6%), compared to the methylimidazolium IL 24 (31%). We propose this is in part due to a higher share of carbon content of the proposed transformation product (PTP) of IL 23 (23 = 18C vs. 23 PTP = 14C, 22% decrease in C) compared to 24 PTP (24 = 12C vs. 24 PTP = 8C, 33% decrease in C), which are both assumed to persist (Fig. 3). While hydrolysis of all three ester groups in both ILs 23 and 24 to give the fully hydrolysed 23 PTP and 24 PTP is reasonable under the test conditions, only the biodegradation value for IL 24 (31%) supports this complete ester hydrolysis. The biodegradation of IL 23 (6%) is so low that significant biotic ester hydrolysis cannot be stated. A comprehensive LC-MS study would be required to confirm the structure of transformation products and was beyond the scope of the study. In contrast to the result reported herein are the high levels of biodegradation reported by Coleman *et al.*³⁴ (Fig. 4, CO₂ Headspace test ISO 14593), Jordan *et al.*³⁵ and Haiß *et al.*³⁷ (Fig. 5, CBT) for several phenyl containing amino acid ILs.

The effect of a phenyl group attached to the same carbon atom as the headgroup can be evaluated by comparing the biodegradation of ILs 4 and 8 to previously reported ILs with pyridinium headgroups (28) and nicotinic acid derived headgroups (29 and 30) (Fig. 6).⁷³ The nicotinic acid derived IL (8) presented herein gave significantly lower levels of biodegradation (31%) than the readily biodegradable nicotinic acid derived ILs 29 and 30 (72 and 84% respectively). Also, pyridinium IL 4 gave significantly lower levels of biodegradation (16%) than the comparative readily biodegradable pyridinium IL 28 (87%). This suggests that α -substitution of the N-heterocycle with a phenyl group (from the mandelic acid starting material) has a significant negative impact on the biodegradability of the ILs. We propose this is a new rule of thumb to be considered when designing biodegradable compounds. It should also be noted that even lower levels of biodegradation were recorded for the amide ILs 9 and 10, which were expected for reasons previously described.

The comparison of the theoretical ester/amide biodegradation values to the experimental values for ILs 1–10 (Table 4) show that a good prediction for the ester ILs 1–8 is obtained. This analysis allows for the conclusion that the biodegradation of the ester ILs is most likely occurring only at the ester bonds. A clear trend is observed across the series in the order of methyl ester ILs (5–8% biodegradation), ethyl ester ILs (16–20% biodegradation), *n*-butyl ester ILs (21–27% biodegradation) and ethyl/*n*-butyl ester IL 8 (31% biodegradation). When considering the confidence levels of the test, even a prediction of 6% lower theoretical biodegradation compared to that observed experimentally (IL 3) is likely not significant enough to suggest that additional parts of the molecule (*i.e.* the 1-methylimidazolium ring) are breaking down. This conclusion is additionally supported by the literature which shows that 1-methylimidazolium based ILs are often poorly biodegradable.⁷⁴

The calculated theoretical biodegradation values for the 1-methylimidazolium *n*-butyl amide IL (9) and the pyridinium *n*-butyl amide IL (10) are much higher than the biodegradation results obtained experimentally (+25 and +22% respectively).

Table 5 PTPs for ILs 1–8 (31–34)

Parent IL	PTPs
1, 3, 5	31
2, 4, 6	32
7	33
8	34

The calculation is made assuming that biodegradation of the amide is occurring; however, from the experimental values we can see that for IL 9 and 10 no biodegradation occurred at all under the conditions of the CBT in the 28 day period. This is in accordance with literature that reports amides to have poor levels of biodegradation.⁶⁸ Thus, the calculation overestimates the level of biodegradation expected for the amide ILs as the experiments show that the amides did not biodegrade under the CBT conditions over 28 days.

Biodegradation proposed transformation products

When a compound biodegrades a number of biodegradation transformation products are produced that might not be accessible to further biodegradation (so called persistent transformation products).¹⁴ The PTPs of ILs 1–8 formed by ester breakdown are the carboxylic acid derivatives of the parent ILs (23–26) (Fig. 7 and Table 5). Amide ILs 9 and 10 give the same PTPs as the ester ILs (31 and 32 respectively), although no biodegradation was observed in the CBT. Alkylamines have previously shown high levels of degradation in biodegradation tests (oxygen consumption, colorimetric, total organic carbon (TOC) and CO₂ production measurements).⁶⁴ We propose that if amide hydrolysis had occurred the biodegradation of *n*-butylamine would have been detected by the CBT. In our test there is no evidence of this breakdown. Transformation products can be detected after biodegradation studies by carrying out LC-MS, MS/MS, LC-HRMS and/or NMR analysis on the resultant biodegradation stream.^{37,75,76} An analysis of the toxicity of the

transformation products is also always recommended as they may be more toxic than the parent compounds.⁷⁷ For toxicity studies to be undertaken, synthesis of the individual PTPs needs to be carried out. However, with the same PTPs presenting for multiple ILs, only a small number of compounds would need to be synthesised to obtain toxicity/biodegradation data on the transformation products for multiple parent compounds.

The 3-(ethoxycarbonyl)pyridinium *n*-butyl ester IL (8) contains two ester groups which may have different rates of biodegradation in the CBT, leading to the production of two additional transformation products (35 and 36) (Scheme 3). A comparison of the theoretical ester/amide biodegradation of IL 8 to the experimental biodegradation (30 and 31% respectively) shows that they are very similar. This suggests that the biodegradation of IL 8 did not stop at either of the mono ester transformation products (35 and 36) during the 28 day period of the CBT. Both biodegradation pathways may have the same kinetic rate leading to the predominant transformation product 34 (Scheme 3) at the end of the CBT. However, a more detailed LC-HRMS study would be required to determine which of the pathways are followed.

Conclusion

A series of ten bromide ILs (1–10) derived directly from the biorenewable natural product mandelic acid was synthesised. The series was selected based on diverse structural features (including *n*-alkyl chains, ester/amide bonds and various N-heterocyclic headgroups), thus allowing for the investigation of their effect on IL toxicity and biodegradation. None of the ILs showed high antimicrobial activity to the twenty bacterial and fungal strains screened as a preliminary toxicity assay. However, moderate toxicity was observed for the 1-methylimidazolium ethyl ester (3) against several of the bacterial strains. Subsequent IC₅₀ determination showed that the majority of the ILs presented with low toxicity towards one Gram-positive bacterial strain and four Gram-negative bacterial strains when high IL concentrations (up to 200 mM) were evaluated. IL toxicity across all bacterial strains increased as the alkyl chain length increased in the order methyl ester < ethyl ester < *n*-butyl ester/amide. Despite observing in general a higher antimicrobial activity for the ILs (1–10) compared to the previously synthesised highly oxygenated mandelic acid derived ILs (19–22), it is a substantial positive result that the ILs herein do not represent a large increase in the level of inhibition. Low toxicity ILs (1–10) were synthesised in a shorter and more efficient synthesis directly from mandelic acid (*c.f.* 19–22) satisfying the 4th and 7th principles of green chemistry: designing safer chemicals and the use of renewable feedstocks (respectively).

The biodegradation studies of the ILs in the CBT showed biodegradation in the range of 5–31% in 28 days for the mandelic acid derived ester ILs (1–8). The mandelic acid derived amide ILs 9 and 10 demonstrated no biodegradation in the CBT (0 and 1% in 28 days, respectively). The CBT results of the *n*-butyl ester ILs 5–8 were in the narrow range (21–31%) which does not support a detailed analysis of the effect of the

Scheme 3 Proposed biodegradation pathways for IL 8.

headgroup. The biodegradation pathway proposed for the ILs is through ester alkyl chain biodegradation to a carboxylic acid derivative. This conclusion is based on previous results in the literature, and was reinforced by comparing the results of a theoretical ester/amide biodegradation calculation to the results obtained in the CBT.

An overall goal is to develop ILs which biodegrade fully (*i.e.* mineralise completely) by breaking down *via* transient transformation products, and to expand our understanding of rules of thumb to design biodegradable chemicals. As we and others work towards this goal, persistent transformation products have been proposed and identified.^{13,35,37} It is an ongoing challenge to design from the outset a series of compounds (which includes predicted transformation products) that lead to the greatest optimisation of a structure activity relationship (SAR) for biodegradation (mineralisation).

Biodegradation studies of ILs containing a phenyl ring demonstrate that examples are known which can pass readily biodegradable tests (25, 26, 28, 29, 30), can be classed as mineralisable (27), or not pass the readily biodegradable tests (23). The mandelic acid derived ILs (1–10) fall into the latter category and can be included in the rules of thumb for the design of biodegradable ILs.
